MMWR™
MORBIDITY AND MORTALITY
WEEKLY REPORT

Outbreak of Rift Valley Fever — Saudi Arabia, August–October, 2000

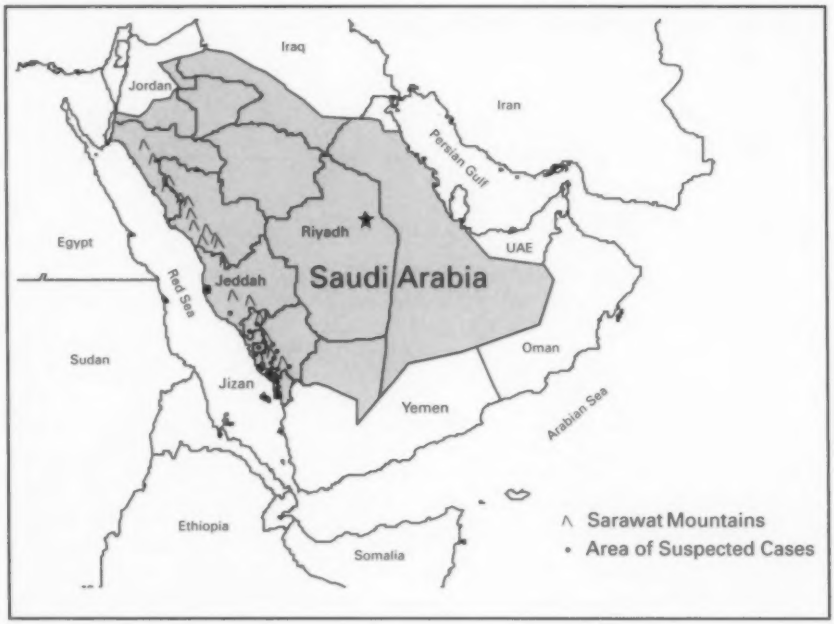
On September 10, 2000, the Ministry of Health (MOH), Kingdom of Saudi Arabia, and subsequently the Ministry of Health of Yemen received reports of unexplained hemorrhagic fever in humans and associated animal deaths from the southwestern border of Saudi Arabia and Yemen. Signs and symptoms of ill persons included low grade fever, abdominal pain, vomiting, diarrhea, jaundice with liver and renal dysfunction often progressing to disseminated intravascular coagulation, hepatorenal syndrome, and death. On September 15, using ELISA (antigen detection and IgM), polymerase chain reaction, virus isolation, and immunohistochemistry, CDC confirmed the diagnosis of Rift Valley fever (RVF) in all four serum samples submitted from Saudi Arabia. This report summarizes the preliminary results of the collaborative epidemiologic investigation performed by the Saudi Arabian MOH, CDC, and the National Institute of Virology, South Africa, of the first confirmed occurrence of RVF outside Africa.

As of October 9 in Saudi Arabia, 316 persons with suspected severe RVF* have been reported from primary health-care centers and hospitals. All suspected severe cases have been hospitalized for care and management. Of the 316 case-patients, 245 (78%) were male; the median age was 46 years (range: 11–95 years); 15 (5%) were aged <16 years; 253 (80%) were Saudi citizens and 63 (20%) were Yemen citizens. At least 66 (21%) patients have died. Suspected severe case-patients investigated to date resided in or visited the floodplains of the wadis (i.e., seasonal riverbeds) that emanate from the foothills of the Sarawat mountains and extend south of Jeddah to the border of Yemen (Figure 1). Of the 316 suspected cases, 304 (96%) have been reported from the southern coastal province of Jizan (1992 population: 860,000) and the contiguous Asir and Al

*Screening case definition for RVF: unexplained illness >48 hours in duration associated with three times elevation in transaminases (aspartate aminotransferase, alanine aminotransferase, and gamma glutamyl transpeptidase) or clinical jaundice; or unexplained illness >48 hours in duration associated with abortion or bleeding manifestations (e.g., from puncture sites, ecchymosis, petechiae, purpura, epistaxis, gastrointestinal bleeding, or menorrhagia); or unexplained acute visual loss or scotoma; or unexplained illness >48 hours in duration associated with neurologic manifestations (e.g., vertigo, confusion, disorientation, amnesia, lethargy, hallucination, meningismus, choreiform movements, ataxia, tremor, convulsions, hemiparesis, decerebrate posturing, locked-in syndrome, or coma); or unexplained illness >48 hours in duration associated with fever, diarrhea, nausea, vomiting, or abdominal pain and any one of the following laboratory values: 1) hemoglobin <8 gm/dL; 2) platelets <100,000 mm^3 ($<10 \times 10^{10}$/L); 3) LDH 2 x upper limit of normal; 4) creatinine >150 mol/L; 5) CPK 2 x upper limit of normal; or unexplained death with history of fever, lethargy, diarrhea, abdominal pain, nausea, vomiting, or headache in the preceding 2 weeks.

Rift Valley Fever — Continued

FIGURE 1. Area of reported suspected cases of Rift Valley fever — Saudi Arabia, August–October 2000



Quenfadah health regions. Cases from four other health regions have documented travel to these areas. The onset of the earliest suspected case was August 27 (Figure 2).

The activities of the MOH, Ministry of Agriculture and Water, and Ministry of Municipalities to contain the outbreak included an intensive mosquito-control program; restriction of movement of domestic animals; a comprehensive educational campaign to eliminate contact with sick animals and mosquitoes (including provision of free permethrin-impregnated bednets); encouragement to seek early medical evaluation of persons with febrile illnesses; and information for health-care providers on the clinical presentation and management of suspected cases. Studies are in progress to identify risk factors for infection, severe disease, and mortality. Animal, human, and vector surveillance is being strengthened throughout the country, including establishment of central human and veterinary virology laboratories in Riyadh and Jizan, respectively. A kingdomwide survey among domestic ungulates, primarily sheep and goats, is under way to define the boundaries for a veterinary vaccination program. Additional studies are planned to assess the magnitude of the outbreak, to define infection rates among high-risk groups, such as veterinarians and slaughterhouse workers, and to determine evidence for nosocomial transmission.

Editorial Note: RVF is a mosquitoborne zoonotic viral disease predominantly causing abortion and deaths of young animals (e.g., sheep and goats) (*1*). Epizootic and epidemic transmission is associated with periodic heavy rainfall. Human infection is predominately not apparent or is associated with a brief self-limited febrile illness. However, complications such as retinitis, hemorrhagic fever, or encephalitis occur in some patients (approximately 15%, 1%, and 1%, respectively) (*1*). Transmission is primarily by contact with infected animal body fluids and mosquito bites, although virology laboratory workers also are at risk. Person-to-person transmission has not been reported. The Saudi Arabian MOH is evaluating the feasibility of a randomized, placebo-controlled trial using intravenous ribavirin in patients with suspected severe RVF. Although ribavirin has not been administered to humans with RVF, evidence suggests its efficacy in animal models (*2*). Intravenous ribavirin has been shown to treat effectively other viral hemorrhagic fevers, including Lassa fever, hemorrhagic fever with renal syndrome, and Crimean-Congo hemorrhagic fever (*2*).

Rift Valley Fever — Continued

This outbreak on the Arabian Peninsula represents the first cases of RVF outside Africa. The potential of RVF virus to establish transmission and cause disease in new areas first was documented during its emergence in Egypt in 1977; previously, the disease was limited to sub-Saharan Africa. The virus isolated from the blood of the first patients had a RNA sequence similar to the RVF viruses isolated during 1997–1998 East African outbreaks (*3*). Cross-sectional community surveys for asymptomatic and milder illnesses and laboratory evidence of infection are in progress to assess the magnitude and geographic extent of infection.

Measuring Childhood Asthma Prevalence Before and After the 1997 Redesign of the National Health Interview Survey — United States

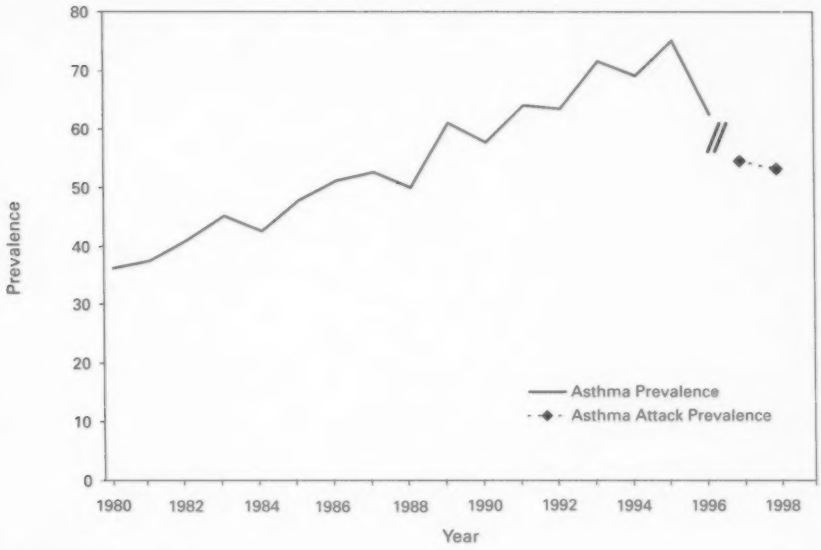
Asthma is the most common chronic disease of childhood and a leading cause of disability among children (*1,2*). Since 1980, asthma prevalence has increased dramatically in children (*3,4*). The National Health Interview Survey (NHIS), the principal source of asthma prevalence data for the United States, was redesigned in 1997. This report presents NHIS data from 1980–1998 to examine the effect of the redesign on measuring trends in asthma prevalence overall and among age and racial subgroups of children. The findings indicate that although asthma prevalence estimates for 1997–1998 are lower than those preceding changes in the survey design, estimates after 1997 are not comparable to previous estimates. Additional data are needed to establish a new trend after 1997.

NHIS is an ongoing household survey of a representative sample of the noninstitutionalized civilian U.S. population. For children aged <18 years, a knowledgeable adult family member, usually a parent, acts as a proxy respondent. Before 1997, one sixth of NHIS-sampled households were asked about chronic respiratory conditions, including asthma (approximately 4500 children in most years). Information on asthma was obtained by the question, "During the past 12 months, did anyone in the family have asthma?" Field testing of a redesigned survey began in 1996, resulting in a 40% decrease in the survey sample compared with previous years. Starting in 1997, information about asthma was collected for a randomly selected sample child in every household containing a child (approximately 14,000 children each year). The redesigned NHIS also specifically obtained information on asthma diagnoses by asking "Has a doctor or other health professional ever told you that your child had asthma?" To determine current asthma attack prevalence, persons answering yes were then asked "During the past 12 months, has your child had an episode of asthma or an asthma attack?" National estimates and standard errors were calculated using SUDAAN.

Overall, asthma prevalence among persons aged 0–17 years increased approximately 5% each year during 1980–1995 (Figure 1). The 1996 estimate of 62 per 1000 children (standard error [SE]=4.9) was 17% lower than in 1995 (75 [SE=4.3]). On the basis

Childhood Asthma — Continued

FIGURE 1. Prevalence* of childhood asthma among persons aged 0–17 years, by year — National Health Interview Survey (NHIS), United States, 1980–1998†



* Per 1000 population.
† NHIS was redesigned in 1997, resulting in a discontinuation of the trend.

of the redesigned survey, the 1997 and 1998 prevalence estimates were 54 and 53, respectively, representing the beginning of a new trend.

During 1980–1996, prevalence among black non-Hispanic children was greater than that among either white non-Hispanic or Hispanic children (Table 1). The gap between non-Hispanic black and white children widened progressively, from a 15% higher prevalence among blacks during 1980–1981 to 26% during 1995–1996. In the redesigned survey, when compared with white non-Hispanic children, asthma attack prevalence among black non-Hispanic children was 29% higher in 1997 and 31% higher in 1998. From 1985–1986 to 1995–1996, prevalence among Hispanic children increased rapidly. Compared with non-Hispanic white children, asthma prevalence among Hispanic children was 38% lower during 1985–1986 but 17% greater during 1995–1996. In 1997 and 1998, asthma attack prevalence among Hispanic children was similar to that among non-Hispanic white children. Within the three pediatric age groups, prevalence generally increased during 1980–1996. Prevalence also increased with age; children aged ≥5 years had a higher prevalence than younger children. This pattern was similar for asthma attack prevalence in 1997 and 1998, although the difference between children aged 0–4 years and older children was not statistically significant in 1998.

§ Data for 1997 and 1998 were affected by a redesign of NHIS.
¶ Not available. White and black estimates for 1980–1981 include Hispanic ethnicity.

Editorial Note: Although estimates of asthma prevalence appear lower after 1995 than in earlier years, changes in the number of children surveyed and in the survey design in 1996 and 1997 preclude drawing conclusions about recent changes in childhood asthma. The 1996 survey had a smaller sample size than previous years, resulting in a greater sampling error. The redesigned survey specifically collected information about medical diagnosis of asthma and the frequency of asthma attacks.

The redesigned survey also may have differentially affected measurement of asthma prevalence among subgroups in the pediatric population. Among age subgroups, the pattern of asthma attack prevalence appeared unaffected: in 1997 and 1998, children aged 0–4 years continued to have lower asthma attack prevalence compared with older children. However, among race/ethnicity subgroups, asthma attack prevalence estimates declined more for Hispanic than non-Hispanic children.

Although the redesign of NHIS created a break in the trend of asthma prevalence, the changes will enable researchers and policy makers to better understand national trends in asthma prevalence. In contrast with the previous question, the redesigned survey measures physician-diagnosed asthma and produces a more specific estimate. In addition, estimating asthma attack prevalence is more helpful for planning public health interventions by measuring the population at risk for serious outcomes from asthma, including hospitalization and death.

To promote comparability of surveillance data, the Council of State and Territorial Epidemiologists (CSTE) recommends that a uniform case definition be used by all systems collecting data on self-reported asthma. The 1998 CSTE uniform case definition of self-reported asthma includes a positive response to the survey question, "Did a doctor or other health professional ever tell you (or any household member) that you (they) had asthma?" and a positive response to any one of the following: a) "Do you (or the household member) still have asthma?" b) "Have you (or the household member) taken prescription medications for asthma during the past year?" or c) "Have you (or the household member) had a wheeze episode in the past year?" In addition to the 1997 changes, the 2001 NHIS survey will be modified to adopt a similar case definition by including the question "Do you still have asthma?" Standardized questions for adult asthma prevalence, consistent with the case definition recommended by CSTE, were added to the

Childhood Asthma — Continued

Behavioral Risk Factor Surveillance System (BRFSS) core module in 2000 and standard questions for child prevalence were added as part of a 2001 module. As a result, three comparable asthma questions for children in both the NHIS and the BRFSS surveys will allow comparisons between local and national asthma prevalence estimates in 2001. Improvements in national and state surveillance will help to identify the factors underlying development and exacerbation of asthma and to develop and target more effective treatment and prevention strategies.

Outbreak of *Escherichia coli* O157:H7 Infection Associated With Eating Fresh Cheese Curds — Wisconsin, June 1998

On June 15, 1998, the Division of Public Health, Wisconsin Department of Health and Family Services, was notified of eight laboratory-confirmed and four suspected *Escherichia coli* O157:H7 infections among west-central Wisconsin residents who became ill during June 8–12. This report summarizes the outbreak investigation, which implicated fresh (held <60 days) cheese curds from a dairy plant as the source of infection.

A primary case was defined as the first laboratory-confirmed case in a household; a secondary case was one that occurred 3–8 days after a primary case in the same household. A matched case-control study was conducted to assess potential sources of infection. For the purposes of the case-control study, a case was defined as culture-confirmed illness among residents of Chippewa and Eau Claire counties with illness onset during June 7–18. For each case-patient, two community controls matched by sex and age group (range: from <10 years within 2 years to ≥10 years within 5 years) were interviewed by telephone. Case-patients and controls were interviewed about food exposures and potential risk factors for *E. coli* O157:H7 infection within 7 days before onset of illness.

In response to the case-control study, the Wisconsin Department of Agriculture, Trade, and Consumer Protection visited dairy plant A to collect cheese samples, raw ingredients, and packaging materials; to review employee food handling and hygienic practices; and to assess potential sources of contamination from raw milk. Product and environmental samples (e.g., vat surfaces and floor drains) from the dairy plant were screened for phosphatase activity to identify evidence of raw milk.

Fifty-five laboratory-confirmed case-patients were identified, including two from secondary households. Case-patients were from seven Wisconsin counties (27 from Chippewa and 16 from Eau Claire counties); two case-patients were visiting from out of state. Median age was 27 years (range: 15 months–90 years) and 37 (67%) were female. The most frequently reported symptoms included bloody diarrhea (55 [100%]), cramps (50 [91%]), fatigue (39 [71%]), and nausea (38 [69%]). Mean duration of diarrhea was 5.1 and 4.5 days for 25 hospitalized and 30 nonhospitalized case-patients, respectively.

Cheese Curds — Continued

Eating fresh cheese curds during June 1–17 was reported by all 24 case-patients in Chippewa and Eau Claire counties and eight (18%) of 45 controls (matched odds ratio=undefined; 95% confidence interval=20.6–infinity). Illness was not linked to eating other cheese products (e.g., shredded, sliced, block, or string cheese). Of the 43 laboratory-confirmed case-patients whose cheese curd source could be identified, all had eaten fresh cheese curds produced at dairy plant A; 19 had purchased the curds from an unrefrigerated display at plant A, and 24 had purchased them refrigerated from retail stores that received shipments from plant A. Fifteen (50%) of 30 case-patients who recalled the purchase date had bought the curds on June 5 or 6. The median number of curds eaten was eight (range: one–28), the equivalent of approximately 1.6 oz of cheese.

Thirty-five specimens from plant A that were produced during the outbreak were tested: nine environmental samples, 18 unopened cheese samples, six opened retail packages of curds, and two unopened retail packages of curds. Five of the six opened retail packages of curds and four of the 18 unopened cheese samples were positive for nonbacterial phosphatase (Scharer method). *E. coli* O157:H7 was isolated from an opened package of curds that had been served at a party attended by nine persons with culture-confirmed illness. The contents of this package tested positive for nonbacterial phosphatase. Among 44 *E. coli* O157:H7 case-patient isolates available for pulsed-field gel electrophoresis, 42 were indistinguishable from each other and from the curd isolate.

Dairy plant A had produced four or five vats of pasteurized cheddar and Colby cheese products 5 days a week since 1977. Each vat yielded approximately 1500 pounds of cheese that was pressed into 40-lb blocks, daisies (rounds of cheese), or was packaged as fresh cheese curds. Dairy plant A also produced unpasteurized (raw milk) cheddar cheese daisies every June as part of Dairy Month. Certain raw milk cheese products can be produced and sold legally as long as the cheese is held at ≥35 F (≥1.7 C) for at least 60 days before it is sold*. Curds are sold fresh (held <60 days); therefore, curds must be made with pasteurized milk. At least one 1500-lbs vat of raw milk cheddar cheese was made on May 27 and June 2–5. These vats were used inadvertently to make fresh curds, which were incorrectly labeled "pasteurized" cheddar cheese curds, and distributed and sold in six Wisconsin counties.

Reported by: J Durch, MPH, T Ringhand, MPH, Chippewa County Dept of Public Health, Chippewa Falls; K Manner, M Barnett, Wisconsin Dept of Agriculture, Trade, and Consumer Protection; M Proctor, PhD, S Ahrabi-Fard, MS, Communicable Disease Epidemiology Section; J Davis, MD, State Epidemiologist for Communicable Disease, Wisconsin Div of Public Health. D Boxrud, Minnesota Health Dept. Foodborne and Diarrheal Diseases Br, Div of Bacterial and Mycotic Diseases, National Center for Infectious Diseases; and an EIS Officer, CDC.

Editorial Note: Cheese is made in vats by coagulating milk with enzymes and/or acids. After whey is drained, the large cheese clumps are removed and milled into curds, salted, and packaged in small plastic bags for sale. Raw milk consumption has been associated with campylobacteriosis, salmonellosis, *E. coli* O157:H7, yersiniosis, listeriosis, tuberculosis, brucellosis, cryptosporidiosis, and staphylococcal enterotoxin poisoning (*1*). In 1950, the U.S. Food and Drug Administration (FDA) required manufacturers of soft and fresh cheeses to use pasteurized milk and allowed raw milk to be used only for certain aged cheeses (*2*). In 1986, *E. coli* O157:H7 illness was associated with consuming raw milk (*3*). In 1987, FDA banned the interstate sale of raw milk in retail packages. During 1973–1992, 40 (87%) of 46 raw milk-associated outbreaks occurred in the 28

*Code of Federal Regulations Title 21, Part 133.

Cheese Curds — Continued

states that permitted the intrastate sale of raw milk (*4*). During the same period, 11 of 32 cheese-associated outbreaks were attributed to contamination before distribution (*5*).

This outbreak investigation illustrates the hazards of using raw milk to produce commercial products that may lead to mislabeling or contaminating pasteurized product by equipment or ingredients. This practice can result in pasteurized products contaminated by equipment or ingredients and in product mislabeling. States that allow the sale of unpasteurized milk or dairy products made from unpasteurized milk should take appropriate steps to reduce the risk for contamination and mislabeling to prevent similar outbreaks.

Enterovirus Surveillance — United States, 1997–1999

Enteroviruses account for an estimated 10–15 million symptomatic infections in the United States each year (*1*). At present, 66 serotypes of enteroviruses are recognized, including three poliovirus serotypes (*2*). A range of diseases is associated with nonpolio enterovirus infections, including aseptic meningitis, encephalitis, neonatal enteroviral disease, myocarditis, pericarditis, chronic infections among persons with compromised immune systems, poliomyelitis-like illness, hand-foot-and-mouth disease, nonspecific upper respiratory disease, and other manifestations (*3*). This report summarizes data from the National Enterovirus Surveillance System (NESS) and describes temporal trends of reported enterovirus infections in the United States during 1997–1999.

From January 1997 through December 1999, state public health laboratories reported to CDC 1741 enterovirus isolates, including 1672 isolates of nonpolio enteroviruses (Table 1) and 69 isolates of vaccine-related polioviruses. The number of states reporting enterovirus isolations declined from 14 in 1997 to eight in 1999.

Of the 1672 nonpolio enterovirus isolates, echovirus 30 was the predominant serotype and accounted for 27.5% of all isolates, followed by echovirus 11 (13.8%), echovirus 9 (8.7%), and echovirus 6 (6.9%). Enterovirus serotype was reported as unknown for 13.1% of the isolates. The 15 most common serotypes accounted for 88.6%–98.2% of all isolates each year. Of the 63 known nonpolio enterovirus serotypes, 38 were reported during 1997–1999. Of these, 15 serotypes (coxsackie viruses A9, B2, B3, B4, B5; echoviruses 4, 5, 6, 9, 11, 16, 18, 25, 30; and enterovirus 71) have been reported in each of the 3 years. Twelve of these serotypes were among the 15 most common enteroviruses reported during 1997–1999.

15 most frequent serotypes		*88.6*		*98.2*		*96.9*		*93.7*

Enterovirus Surveillance — Continued

During 1997–1999, the proportion of isolates for some serotypes, such as echoviruses 6, 7, 11, and 30, varied widely, and the proportion of isolates for some other serotypes (e.g., coxsackieviruses B2 and B4) remained relatively low but constant.

In addition to nonpolio enteroviruses, 69 isolates of vaccine-related polioviruses were reported (3.9% of all enterovirus isolates). The number of vaccine-related poliovirus isolates declined from 47 (8.2%) in 1997 to 19 (2.3%) in 1998, to three (0.8%) in 1999.

Of the 25.3% of reports that included clinical information, most of the reported diagnoses were aseptic meningitis (37.6%) or respiratory illness (9.3%) and a smaller percentage were encephalitis (4.1%) and carditis and paralytic illness (0.2%). The source for enterovirus isolation was the cerebrospinal fluid (44.2% of reports), a stool specimen or a rectal swab (24.2%), a nasopharyngeal specimen (20.9%), and a urine sample (1.1%). For 9.6% of reports, the source of enterovirus isolation was not noted. Children aged <1 year accounted for 45% of all reported enterovirus isolates.

Reported by: State virology laboratory directors. Respiratory and Enteric Viruses Br, Div of Viral and Rickettsial Diseases, National Center for Infectious Diseases, CDC.

Editorial note: To monitor temporal patterns of enterovirus circulation, state public health laboratories voluntarily report enterovirus isolates by serotype to CDC through NESS. The findings in this report are consistent with previous observations on temporal variability of predominant serotypes. Some serotypes appear to circulate endemically and others circulate in a cyclical fashion with epidemic years followed by years with decreased activity (*1*). Of the 15 most common serotypes during 1997–1999, 10 serotypes (echoviruses 30, 11, 9, 6, and 7; coxsackieviruses B2, A9, B3, and B4; and enterovirus 71) were among the most common enteroviruses during 1993–1996 (*4*). Of these, only enterovirus 71 was not included among the predominating serotypes during 1970–1983 (*1*). The proportion of less common serotypes declined from 17.8% during 1993–1996 (*4*) to 6.3% during 1997–1999. The proportion of enterovirus isolates of unknown serotype increased from 3.8% of all isolates during 1993–1996 (*4*) to 13.1% during 1997–1999.

The decline in numbers of vaccine-related poliovirus isolates during 1997–1999 probably resulted from declining use of oral polio vaccine (OPV) in the United States. To prevent cases of vaccine-associated polio, CDC's Advisory Committee on Immunization Practices recommended transition from an all-OPV schedule to a sequential schedule of polio vaccination (i.e., two doses of inactivated polio vaccine followed by two doses of OPV) beginning in 1997 (*5*) with further narrowing of the options for administering OPV beginning in 1999 (*6*).

Enterovirus surveillance data provide information for detecting major temporal trends in enterovirus circulation in the United States. However, the data may not be representative of the general U.S. population because of the limited number of reporting laboratories. In addition, this number has declined from 25 in 1993, to 14 in 1996 (*4*), to eight in 1999. This decline is of concern, especially at a time when enterovirus antiviral drugs are being developed (*7,8*). Because of the variability in susceptibility of different enterovirus serotypes to some antiviral drugs (*9*), data about the circulating serotypes will be helpful in considering the impact of these drugs on enterovirus disease. Enterovirus surveillance data also are important for use in confirming that wild poliovirus has been eradicated from the United States. Finally, new methods, such as the polymerase chain reaction assay and sequencing studies, are improving the ability to diagnose and serotype enterovirus infections (*2,10*) and may improve surveillance for enterovirus serotypes.

Enterovirus Surveillance — Continued

CDC is considering changes to promote more complete and timely reporting of enterovirus surveillance data and to include new approaches for detecting and serotyping enterovirus infections.

Erratum: Vol. 49, No. 39

In the Notice to Readers, "Updated Recommendations From the Advisory Committee on Immunization Practices in Response to Delays in Supply of Vaccine for the 2000–01 Season," on page 889 in the last sentence of the second paragraph, an age range was incorrect. The sentence should read, "More than 18,000 (>90%) of these deaths and approximately 48,000 of the P&I hospitalizations per year occur among persons aged ≥65 years who are at highest risk for influenza-related complications."

Erratum: Vol 49, No. 37

In the Table, "Reported cases of notifiable diseases, by geographic division and area, United States, 1999" on page 851, population and disease incidence data for Nevada were deleted inadvertently. The data should have been reported as follows: Total resident population (in thousands), 1,809; AIDS, 242; Botulism, foodborne 0; Botulism, infant 1; Brucellosis, 0; and Chancroid, 0.

TOTAL	11,191¶	7,663	2,210	765	294	249	714

U: Unavailable. -:No reported cases.
*Mortality data in this table are voluntarily reported from 122 cities in the United States, most of which have populations of ≥100,000. A death is reported by the place of its occurrence and by the week that the death certificate was filed. Fetal deaths are not included.
†Pneumonia and influenza.
§Because of changes in reporting methods in this Pennsylvania city, these numbers are partial counts for the current week. Complete counts will be available in 4 to 6 weeks.
¶Total includes unknown ages.

The *Morbidity and Mortality Weekly Report (MMWR)* Series is prepared by the Centers for Disease Control and Prevention (CDC) and is available free of charge in electronic format and on a paid subscription basis for paper copy. To receive an electronic copy on Friday of each week, send an e-mail message to *listserv@listserv.cdc.gov*. The body content should read *SUBscribe mmwr-toc*. Electronic copy also is available from CDC's World-Wide Web server at *http://www.cdc.gov/mmwr* or from CDC's file transfer protocol server at *ftp://ftp.cdc.gov/pub/Publications/mmwr*. To subscribe for paper copy, contact Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402; telephone (202) 512-1800.

Data in the weekly *MMWR* are provisional, based on weekly reports to CDC by state health departments. The reporting week concludes at close of business on Friday; compiled data on a national basis are officially released to the public on the following Friday. Address inquiries about the *MMWR* Series, including material to be considered for publication, to: Editor, *MMWR* Series, Mailstop C-08, CDC, 1600 Clifton Rd., N.E., Atlanta, GA 30333; telephone (888) 232-3228.

All material in the *MMWR* Series is in the public domain and may be used and reprinted without permission; citation as to source, however, is appreciated.
